Intra-abdominal Ruptured Liver Abscess: Computed Tomography and Clinical Features

Huynh Quang Huy*, Le Cong Tri, Le Quang Minh and Nguyen Quoc Vinh

Abstract

Objectives: The purpose of this study is to describe the computed tomography (CT) and clinical findings of intra-abdominal ruptured liver abscess.

Patients and Methods: The CT and clinical findings of 32 patients who had a confirmed intra-abdominal ruptured liver abscess were analyzed retrospectively at Cho Ray hospital between 2014 and 2018.

Results: 32 patients with a median age of 53.3±15.3 years (range, 24–85 years). There were more men than women in the study, with a male-to-female ratio of 1.9:1. Most of the patients were suffering from abdominal pain (96.9%), malaise and anorexia (96.9%), fever (78.1%), peritonitis (78.1%). The mean size of the liver abscess was 8.4 cm (range, 4.0–14 cm). A single abscess was found in 11 patients, and multiple abscesses were seen in 21 patients. Unilobar involvement was seen in 29 patients, with the right lobe affected more commonly (68.8%, 22 of 32). The abscesses were completely liquefied in 25 patients and gas in the abscess cavity in 7 patients. Free intraperitoneal fluid was seen in all patients.

Conclusion: A knowledge of intra-abdominal ruptured liver abscess is important for an early diagnosis and appropriate management.

Keywords: Liver abscess, ruptured, computed tomography, clinical

Introduction

Liver abscess is a common condition in tropical countries and is associated with significant morbidity and mortality. Traditionally, there are two major classifications of hepatic abscess; pyogenic and amoebic [1,2]. There are various complications associated with hepatic abscesses, of which, rupture of the abscess is the most common [3–5]. Intraperitoneal rupture of liver abscess is a rare but potentially fatal disease, often involving the elderly, who are commonly of poor surgical risk with background of significant medical illness [6,7]. Accurate preoperative diagnosis is difficult and often necessitates exploratory laparotomy for peritonitis [8].

Computed tomography (CT) is an ideal tool for diagnosing hepatic abscesses, and the sensitivity of CT for detecting hepatic abscesses is as high as 97% [9]. On CT, an hepatic abscess appears as a single or multiloculated mass with low attenuation [9]. Early diagnosis and prompt therapy are essential to reduce the morbidity and mortality associated with a pyogenic hepatic abscess. The mortality rate is low when the abscess is confined to the liver; however, the mortality rate is increased when the hepatic abscess extends into the chest, peritoneal cavity, or pericardial cavity [10]. Therefore, the early detection of complications associated with hepatic abscesses is important. In hepatic abscess, various complications have been described [11–13], and the rate of complications was reported to be 10.3% [10]. Reports of complications in pyogenic hepatic abscess are rare, however, and the imaging appearance has been studied in only a small number of patients [13,14]. This article presents the CT and clinical findings of our patients with intra-abdominal ruptured liver abscess.

Patients and Methods

This is a retrospective observational study of patients with intra-abdominal ruptured liver abscess presenting to Cho Ray hospital...
between 2014 and 2018. The study was approved by the Hospital Ethical Board. All diagnosed cases of ruptured liver abscess based on radiology and laparoscopic investigation were included in the study. Details of demographics, clinical features, computed tomography were recorded. Data will be analyzed using SPSS software.

Clinical parameter
Demographic and clinical characteristics comprised age, sex, underlying medical conditions (diabetes mellitus, biliary disorders, hemodialysis, liver cirrhosis, malignancy, immunosuppression, cavities from old calcified echinococcus cysts, simple benign liver cysts), symptoms and signs at presentation and origin of the abscess. Patients receiving empiric therapy with antibiotics prior to admission were also recorded.

Liver CT characteristics
All patients underwent contrast enhanced CT of the liver before laparoscopic drainage of the liver abscess. In some patients, CT studies were also performed during follow-up to assess the size of the abscess cavity, monitor complications. However, we only reviewed the contrast-enhanced CT images obtained before drainage of the liver abscess, for the purpose of this study. The CT examinations were performed using Somatom Sensation 64, Siemens, Germany. The scanning parameters varied during the study period and with different scanners: collimation ranged from 1.25 mm to 7 mm; pitch ranged from 0.75 to 1.5; section thickness ranged from 1 mm to 5 mm. Liver examinations were conducted using 100 ml of intravenous non-ionic iodinated contrast medium (Ultravist, Schering, Berlin, Germany) and dosage was calculated based on the patients’ weight and administered via power injector at a rate of 3 ml/sec. Axial sections of 3-5 mm thickness were reconstructed, reported, and archived.

The scans were reviewed by two radiologists who reached agreement between them. The following features were recorded: (a) lobe involvement (unilobar [right or left] or bilobar); (b) number of abscesses (single or multiple); (c) maximal abscess diameter, with the largest abscess measured when there were multiple abscesses; (d) unilocular or multilocular (presence of ≥1-mm-thick septations), multilocular abscess; (e) solid or cystic appearance (>50% of the abscess cavity appears hypodense or liquefied, with an attenuation value of ≤20 HU) in most of the sections showing the abscess cavity, cystic abscess; (f) gas within the abscess cavity; and (g) spontaneous rupture of the abscess (based on CT and clinical symptoms).

Results
Clinical features
The study group consisted of 32 patients with a median age of 53.3±15.3 years (range, 24-85 years). There were more men than women in the study, with a male-to-female ratio of 1.9:1. Diabetes mellitus was the most common underlying medical condition (25.0%), followed by bacterial pneumoniae (18.8%), hypertension (6.3%), bile duct stones (3.1%) showed in Table 1. None of patients had cirrhosis. Most of the patients were suffering from abdominal pain (96.9%), malaise and anorexia (96.9%), fever (78.1%), peritonitis (78.1%), and other positive clinical signs showed in Table 2.

Liver CT characteristics
The mean time interval between the onset of fever and CT was 8.3 days (range, 1-30 days). The mean size of the liver abscess was 8.4 cm (range, 4.0-14 cm). A single abscess was found in 11 patients, and multiple abscesses were seen in 21 patients. Unilobar involvement was seen in 29 patients, with the right lobe affected more commonly (68.8%, 22 of 32). The abscesses were completely liquefied in 25 patients and gas in the abscess cavity in 7 patients. Free intraperitoneal fluid was seen in all patients. The liver CT characteristics of intra-abdominal ruptured liver abscess was showed in Tables 3 and 4. Figures 1 and 2 are CT-scanned images of the ruptured liver abscess.

Discussion
Liver abscess is an important tropical gastrointestinal disorder [15,16]. Liver abscess can be classified into pyogenic and amebic, both having its serious implications, especially when presented late. In developing countries, it forms a major cause for mortality and morbidity [17,18]. With the advent of modern radiological modalities, diagnosis of hepatic abscess is possible in early stages resulting in nonsurgical management; however, fraction of patients either due to late presentation or refractory disease presents with ruptured liver abscess thereby increasing the mortality, presents with fatal disease
Intraperitoneal rupture is one of the serious complications of liver abscesses. The frequency of intraperitoneal rupture of a liver abscess varies from 2.5% to 17% [22]. Clinically, increasing hepatic tenderness should indicate an impending rupture [22]. Computed tomography may provide important information regarding the extent of intraperitoneal spread of the liver abscess. Dal Mo Yang et al [23] study 81 patients who had a confirmed pyogenic hepatic abscess, the complication was encountered in 3 patients (3.7%), and 2 types could be recognized: a loculated perihepatic abscess (n=2) and diffuse peritonitis (n=1). In diffuse peritonitis secondary to rupture of a hepatic abscess, a large amount of ascites and diffuse thickening of the parietal peritoneum could be seen on CT. Although an amebic peritonitis secondary to rupture of a hepatic amebic abscess showed a poor survival rate despite surgical intervention, all the patients with intraperitoneal rupture of the pyogenic hepatic abscess could be treated with percutaneous drainage and antibiotic treatment.

The most common presentation was abdominal pain (96.9%), malaise and anorexia (96.9%), fever (78.1%), peritonitis (78.1%), nausea/vomiting (62.5%), jaundice and hepatomegaly (15.6% and 12.5%, respectively). This results were comparable to study by Hind S. Alsaiif with the most common presentation was fever and/or chills, followed by gastrointestinal symptoms (eg, gastrointestinal upset, diarrhea, vomiting, nausea, discomfort, pain), respiratory symptoms (eg, cough, dyspnea, chest distress), and jaundice [24]. The clinical features of ruptured liver abscess according to other studies was summarized in the Table 5.

The CT appearance of liver abscess is variable and nonspecific. One or more round or oval low-density lesions 2-16 cm in diameter may be seen. The margin of the abscess may be smooth or nodular, and one or more internal septations may be present. An enhancing wall is common but not universal. However, the wall may not be apparent if unenhanced CT is not performed. Thus, the CT differential diagnosis of amebic liver abscess in the adult includes simple hepatic cyst, infected or hemorrhagic cyst, pyogenic liver abscess,
Unilobar involvement was seen in 54 (81.8%) patients, and a single abscess was found in 95 patients, and multiple abscesses were seen in 36 patients. Unilobar involvement was seen in 11 patients (16.7%). There were 4 (6.1%) patients with liver abscess who experienced a spontaneous rupture of the abscess [27].

A definitive diagnosis of liver abscess requires imaging, with both sonography and CT being useful. Sonography is operator-dependent and the operator may have difficulty picking out a small, solitary abscess. Its sensitivity is around 79%, compared with 98% for CT [28], but emergency bedside sonography may be very useful in making a rapid diagnosis. Kim et al. suggested certain CT characteristics suggestive of a Klebsiella abscess, such as a hairball sign or air-fluid level [29]. However, while such imaging distinctions may be sought, culture and sensitivity results are the key to choosing the appropriate antibiotics.

The advancement in radiologic techniques has been credited with the improvement in mortality rates. Ultrasonography and CT evaluation with contrast remain the radiologic modalities of choice in screening procedures and also can be used as techniques for guiding percutaneous aspiration and drainage. With advancement in multidetector CT scan technology, image quality has improved dramatically, allowing for improved detection. Besides, gallium and technetium radionucleotides can be used in diagnosis.

Our results of liver CT characteristics were comparable to other studies. Alsaif HS et al showed that the median time interval between the onset of fever and CT was 3 days (range, 1–24 days). The median size of the liver abscess was 7 cm (range, 1.7–14 cm). A single abscess was found in 95 patients, and multiple abscesses were seen in 36 patients. Unilobar involvement was seen in 100 patients, with the right lobes affected more commonly (55.0%, 72 of 131). The abscesses were predominantly solid and masslike in 67 patients and cystic in 64 patients. Multilocular appearance of the abscesses was present in 115 patients (87.8%). Thrombophlebitis was present in 30 patients; pylephlebitis, in three; gas in the abscess cavity, in 17; and pneumomilia, in six. Three patients had both gas in the abscess cavity and pneumomilia [24].

A ruptured hepatic abscess is more life-threatening than an unruptured one. A rapid and accurate diagnosis and prompt surgical intervention are essential. Most of the cases had an acute presentation and the right lobe is commonly affected. Abdominal pain was the most common symptom. Computed tomography is an ideal tool for diagnosing hepatic abscesses and its complications.
