Abstract

Background: Dizziness is one of the most common complaints reported to primary care physicians. It is often associated with vestibular dysfunction and typically impacts postural stability. Motion sickness, or motion sensitivity, is stimulated by abnormal spatial orientation and is a common symptom related to dizziness and postural instability. The main cause of the motion sensitivity is aberrant sensory input from the visual, vestibular and somatosensory systems. The aim of this study was to measure the effect of vestibular adaptation exercises on postural stability in young healthy adults with subjective awareness of chronic motion sensitivity.

Methods: Fifty healthy male and female participants between 20 to 40 years of age with chronic motion sensitivity were randomly assigned to either an experimental or control group. Postural stability measurements were taken at baseline and after 6 weeks using computerized dynamic posturography with immersion virtual reality. The experimental group performed daily vestibular adaptation exercises for 6 weeks. The control group was asked to avoid adding any new activities until post assessment to minimize additional vestibular system stimulation.

Results: There was no significant difference between the two groups at baseline in terms of mean age, height, weight, BMI or baseline postural stability scores (p>0.05). Significant differences in mean postural stability scores were observed post intervention in both groups but larger improvements were detected in the experimental group (p=0.002).

Conclusions: Minimal dosage of vestibular adaptation exercises improved postural stability in younger adults with chronic motion sensitivity. Additionally, familiarity of the testing environment during post-test measurements may have contributed to improvements in the control group over time; however, changes were greater in the experimental group.

Keywords: Motion sensitivity, postural stability, vestibular rehabilitation, vestibular adaptation exercises

Introduction

Dizziness is one of the most common complaints reported to primary care physicians [1], which affects 20% to 30% of persons in the general population [2]. It is often associated with vestibular dysfunction and typically impacts postural stability [3]. Motion sickness, or motion sensitivity, is stimulated by abnormal spatial orientation and is a common symptom related to dizziness and postural instability [4]. Gender, age, psychological status and the environment can influence motion sensitivity and postural stability [5]. Many otherwise healthy people experience motion sensitivity during activities including riding roller coasters, boat rides, and/or reading in moving vehicles. As a result, they often avoid these activities because it produces motion sensitivity symptoms including dizziness, nausea, imbalance, and/or blurry vision [5,6]. Additionally, healthy people commonly experience postural instability when exploring their surrounding visual environment while standing on unstable surfaces or when in virtual reality environments [6,7].

Simulated virtual reality and related technologies have been used to demonstrate the relationship between motion sensitivity and postural stability [8]. Akiduki et al., reported that motion sensitivity and postural instability are caused by a visual-vestibular conflict that can be reproduced in virtual reality environments [4].

Akin and Davenport describe motion sensitivity as “a disturbing sense of vertigo or dizziness associated with head movement” that is often the result of vestibular dysfunction [9]. The vestibular system is located in the inner ear and is comprised of three semicircular canals, the utricle and saccule [10]. The vestibular system, along with the visual and somatosensory systems, are the primary systems contributing to motion and postural stability. The afferent input from these systems is processed in the vestibular nuclear complex and coordinates the vestibulo-ocular reflex (VOR) and vestibulospinal reflex, respectively [10]. The VOR maintains stability of the image on the retina during head motions by producing compensatory eye movements for gaze stability [11-14]. The vestibulospinal reflex maintains postural stability through the musculoskeletal system during functional activities [15,16]. Improvement of the VOR can be achieved through vestibular adaptation exercises [17].

Several investigators have reported on the relationship between vestibular dysfunction and the effect of vestibular adaptation exercises on postural stability and dizziness [18-20]. Giray et al., reported significant improvements in symptoms, disability, balance, and postural stability after performing vestibular adaptation exercises in patients with chronic unilateral vestibular dysfunction [18]. According to Hall et al., patients with unilateral vestibular dysfunction had decreased fall risk after performing vestibular adaptation exercises [19]. Additionally, Morimoto et al., used vestibular adaptation exercises to improve gaze stability and postural stability after three weeks in healthy young adults [20]. To the best of our knowledge, the effects of the adaptation exercise on postural stability in healthy young adults with sub-clinical chronic motion sensitivity have not been investigated. Therefore, the purpose of this study was to measure the effects of vestibular adaptation exercises on postural stability in healthy young adults with sub-clinical chronic motion sensitivity. The hypothesis was that vestibular adaptation exercises would improve postural control during virtual reality immersion in participants with chronic motion sensitivity.

Methods
Fifty healthy adults between 20 and 40 years of age with sub-clinical chronic motion sensitivity were recruited for this randomized controlled trial. Participants were recruited using flyers that were posted at our university and by word of mouth. Sub-clinical chronic motion sensitivity was operationally defined as a history of avoiding activities causing dizziness, nausea, imbalance, and/or blurred vision without having a related medical diagnosis. Participants were included in the study if they reported avoiding activities such as reading while a passenger in a moving vehicle, driving on winding roads, boats, airplanes, horseback riding, roller coaster rides and quick movements due to symptoms consistent with motion sensitivity. Participants were excluded if they were currently taking medications causing dizziness or imbalance or had cervical spine orthopedic impairments, vestibular impairments or any neurological pathology. The Loma Linda University Institutional Review Board approved the study. All participants signed an informed consent prior to their beginning the study.

Participants were randomly assigned to either an experimental or control group using a random number table. The experimental group received vestibular adaptation exercises. Both groups received postural stability measurements at baseline and after six weeks using computerized dynamic posturography with immersion virtual reality (CDP-IVR) [21]. Additionally, the experimental group had a follow-up assessment at three weeks post-baseline to progress their vestibular adaptation exercises as tolerated. Participants in the experimental group received daily-automated e-mails using a Qualtrics on-line survey reminding them to perform their exercises. We asked the control group to live their life normally and to avoid adding any new activities that required repeated head movement.

The Bertec Balance Advantage CDP-IVR was used to measure postural stability by calculating center of gravity displacements through strain gauges in the forceplate [22-25]. Postural stability was measured under two conditions. Condition 1 measured postural stability on a stable forceplate with eyes open and focusing on a virtual reality infinite tunnel (Figure 1). The infinite tunnel provided the visual illusion that participants were moving towards the tunnel in an anterior

![Figure 1. Computerized Dynamic Posturography with Immersion Virtual Reality (CDP-IVR).](image-url)
direction. Condition 2 measured postural stability on an unstable forceplate with eyes open focusing on the virtual reality infinite tunnel. Each condition lasted twenty seconds and was repeated three times and an average was calculated.

The Bertec Balance Advantage CDP-IVR calculates postural stability and generates an equilibrium score in the following manner: Signals from the subjects' effort to maintain balance are sampled and analyzed at 1000 Hertz and sway path is computed. The testing protocol calculates the sway path with equilibrium scores quantified by how well the subjects sway remains within the expected angular limits of stability during each testing condition. The following formula was used to calculate the equilibrium score: Equilibrium Score (ES) = ((12.5 degrees - (the taMAX – the taMIN))/12.5 degrees) * 100. The ES uses 12.5° as the normal limit of the anterior-posterior sway angle range, taMAX is theta maximum and taMIN is theta minimum. Sway angle was calculated as follows: Sway Angle = arcsin (COGy/(.55*h)) where y=anterior-posterior sway axis and h=the subject’s height in [cm or inches]. The inverse Sin of the center of gravity was divided by 55% of a person’s height. Subjects exhibiting little sway will achieve equilibrium scores near 100, while subjects whose sway approaches their limits of stability will achieve scores near zero.

Vestibular adaptation exercises have been shown to improve function of the VOR through visual fixation on a target during head movement “head–eye coordination” [17,26,27]. Participants in the experimental group performed the vestibular adaptation exercises one time daily for 5 minutes (Figure 2 and Appendix 1).

**Results**

There was no significant difference between the experimental (N=26) and the control group (N=24) in terms of mean age, height, weight, BMI, the CDP-IVR scores for conditions 1, 2, and average at baseline (p>0.05). Seventeen participants (70.8%) in the experimental group were females compared to 17 participants (65.4%) in the control group (p=0.77) (Table 1).

In the experimental group, there was no significant difference in mean CDP-IVR score between baseline and six weeks later for condition 1 (90.4±1.2 vs. 87.3±1.7, p=0.08) (Figure 3), significant difference in condition 2 (54.2±4.5 vs. 39.9±4.8, p=0.001) (Figure 4), and average of the two conditions (72.3±2.5 vs. 63.6±2.9, p=0.002) (Figure 5). However; in the con-
Figure 5. Mean±SE of postural stability of CDP-IVR for condition average by group over time (N=50) * highly significant for the experimental group (p=0.002); significant for control group (p=0.02).

Discussion

The purpose of this study was to measure the effect of vestibular adaptation exercises on adults with sub-clinical chronic motion sensitivity. Postural stability was measured using CDP-IVR. Results supported the hypothesis that vestibular adaptation exercises would improve postural stability in participants with a history of sub-clinical chronic motion sensitivity.

Motion sensitivity has been defined as “a disturbing sense of vertigo or dizziness associated with head movement” that is often caused by vestibular dysfunction [9]. Furthermore, Akiduki et al., reported that motion sensitivity and postural instability are caused by a visual-vestibular conflict [4]. Specifically, the authors suggest an over-reliance on the visual system with a residual deficit of the vestibular system.

Significant improvements in symptoms, disability, balance, postural stability, and fall reduction have been reported after performing vestibular adaptation exercises in patients with vestibular dysfunction [18,19]. Although the population in the current investigation did not have medically diagnosed vestibular dysfunction, they did report chronic motion sensitivity causing them to avoid certain activities. The authors suggest a sub-clinical vestibular dysfunction exists in some people with undiagnosed chronic motion sensitivity. Given the evidence supporting vestibular adaptation exercises improving vestibular dysfunction, the authors proposed strengthening the vestibular system using adaptation exercises in the experimental group and measuring the effects of postural stability, which is a component of motion sensitivity. The use of CDP-IVR provided a visually challenging sense of moving for study participants with a potential over-reliance on their visual system.

Because of the visually challenging environment caused by the CDP-IVR, familiarization of the testing conditions may explain the improvements observed in both experimental and control groups time [28]. However; the averaged results after 6 weeks between both test conditions and between groups was greater in the experimental group.

Limitations include not using a validated motion sensitivity subject report to correlate subjective and objective findings in adults with chronic motion sensitivity. Akiduki et al., indicated that there was a variance between subjective reports of...
motion sickness or balance and objective postural instability” [4]. However, Cobb and Nichols reported a strong correlation between self-reported symptoms of simulator sickness and between postural instability and a self-reported of motion sickness symptoms [6].

The low dosage of the adaptation exercises may have minimized the improvements observed in our study. Studies recommend that patients begin vestibular adaptation exercises with tolerable velocity, repetitions, and frequency then progress the exercises as able [26,27,29,30]. Additionally, to maximize the benefits of vestibular adaptation exercises, it has been suggested they be designed to reflect the patient-specific function and environment [31]. The range of vestibular adaptation exercise programs has been reported as 3 to 10 weeks [31,32].

Recommendations for future research include the inclusion of a standardized subjective assessment tool to quantify the degree of motion sensitivity and its impact on activities of daily living. Also, more frequent direct observation of the vestibular adaptation exercise program to improve the quality of the exercise performance. Additionally, vestibular adaptation exercises should be progressed including velocity, amplitude, duration, frequency, and directionality of movements to determine if more gains are possible.

Conclusion
Results of this study suggest that a minimal dosage of vestibular adaptation exercises over a 6-week period improves postural stability in younger adults with sub-clinical chronic motion sensitivity. Further research is warranted to determine if additional exercise progression will result in increased gains. Older adult populations should also be included.
